Using This Documentation

- Overview Describes Oracle Solaris troubleshooting issues on both SPARC and x86 platforms
- **Audience** System administrators using the Oracle Solaris 11 release
- **Required knowledge** Experience administering UNIX systems

Product Documentation Library

Documentation and resources for this product and related products are available at http://www.oracle.com/pls/topic/lookup?ctx=E53394.

Feedback

Provide feedback about this documentation at http://www.oracle.com/goto/docfeedback.

· · · CHAPTER 1

Troubleshooting System Crashes

This chapter describes how to prepare for and troubleshoot a system crash in the Oracle Solaris OS.

This chapter covers the following:

- "Crash Files Now Deferred Until After Reboot in Oracle Solaris 11.3" on page 9
- "About System Crashes" on page 10
- "Configuring Your System for Crash Dumps" on page 12

Crash Files Now Deferred Until After Reboot in Oracle Solaris 11.3

Starting with Oracle Solaris 11.3, when a system crashes, the crash dump files might be preserved in memory until after the system reboots. When the system is rebooting, the crash dump files are extracted from memory to the file system that is defined in the dump configuration. Once these files are written, the system automatically reboots to normal multiuser configuration. This process is referred to as a *deferred dump*. Deferred dumps enable systems to return to a running state more quickly after a kernel panic. In addition, deferred dumps specifically benefit systems, such as the SPARC M7 series servers, which may ship without a local disk.

Caution - The first reboot performs the deferred dump. On x86 systems, a second reboot might automatically occur to eliminate any possible performance issues caused by memory fragmentation. Do not interrupt this process. The system is ready for use after the second reboot.

Deferred Dump System Messages

The deferred dump process includes the following system messages:

When the system is performing a deferred dump to memory, a Preserving kernel image in RAM message with a progress bar appears.

- When the system reboots after the panic, a Verified previous kernel image notice followed by a Reconciling deferred dump message with a progress bar appears.
- While savecore is saving the crash dump files to the file system, an Extracting crash dump message with a progress bars display.

Deferred Dump Support

On x86 systems, deferred dumps work in conjunction with the default *fast reboot* feature in Oracle Solaris. Therefore, a deferred dump on an x86 system can function only on platforms supporting fast reboot. For further information about using fast reboots, see "Accelerating the Reboot Process" in *Booting and Shutting Down Oracle Solaris* 11.3 Systems.

Deferred dumps are enabled by default—on SPARC T4 systems that support at least Sys Firmware 8.7 or Sys Firmware 9.4 and later—with sufficient memory to preserve crash dump files until the system reboots.

Even with deferred dump, you should still ensure that the configured dump device has sufficient space to store crash dump information. This is in case a live system crash dump using savecore -L is necessary. Also, crash dump information will be automatically written to the dump device if possible—without being held in memory—in the following situations:

- The platform does not support a fast reboot, or the fast reboot fails.
- The savecore utility is disabled or fails.
- The system is using kernel zones.

For further information about preparing for and responding to system crashes, review this chapter and see the dumpadm(1M) man page.

About System Crashes

System crashes can occur due to hardware malfunctions, I/O problems, and software errors. If the system crashes, it will display an error message on the console and then either preserve a copy of its physical memory in RAM or write a copy of its physical memory to the dump device. The system will then reboot automatically. When the system reboots, the savecore command is executed to retrieve the data from memory or from the dump device and write the saved crash dump files to your savecore directory. These saved files provide invaluable information to aid in diagnosing the problem.

Note - The term "crash dump" refers to the overall result of this process, including the set of crash dump files, where they are located, and how these files are organized and formatted.

System Crash Dump Files

The savecore command runs automatically after a system crash to retrieve the crash dump information from memory or from the dump device and writes the information into a set of files. Afterwards, the savecore command can be invoked on the same system or another system to expand the compressed crash dump files.

Note - Crash dump files are sometimes confused with *core* files, which are images of user applications that are written when the application terminates abnormally.

Crash dump files are saved in a predetermined directory, which by default is /var/crash/. The saving of crash dump files is enabled by default.

Restructured Files

Beginning with the Oracle Solaris 11.2 release, the contents of kernel crash dump files are divided into multiple new files based on their contents. This method enables more granularity in configuration so the files can more easily be accessed and studied.

The crash dump information is written to the set of vmdump-section.n files. The section value is the name of a file section that contains a specific kind of dump information. The n value is an integer which increments every time savecore is run to copy a crash dump and a new crash dump is found on the dump device. Possible files include:

- vmdump-proc.n-Dump file with compressed process pages
- vmdump-zfs.*n* Dump file with compressed ZFS metadata
- vmdump-other.n-Dump file with other pages

Kernel crash dumps were previously stored in vmdump.n, unix.n, and vmcore.n.

The vmdump.*n* and vmcore files store kernel pages—metadata and data—in compressed or uncompressed form, respectively.

For further information, see the dumpadm(1M) and savecore(1M) man pages.

dumpadm and savecore Commands

The dumpadm and savecore utilities configure and manage the creation of a crash dump as follows:

- 1. During system startup, the dumpadm command is invoked by the svc:/system/dumpadm: default service to configure crash dump parameters. It initializes the dump device and the dump content through the /dev/dump interface.
- After the dump configuration is complete, savecore is invoked to check for crash dumps either in RAM or in the dump device and check the content of the minfree file in the crash dump directory. System crash dump files generated by the savecore command are saved by default.
- 3. Dump data is stored in a compressed format on the dump device. Kernel crash dump images can be as large as 128GB or more. Compressing the data means faster dumping and less disk space required for the dump device.
- 4. By default, the installer will create a dedicated dump service. The system will then wait for the savecore command to complete before going on to the next step. On large memory systems, the system can become available before savecore completes.

The savecore -L command enables an administrator to get a crash dump of a system currently running the Oracle Solaris OS. This command is intended for troubleshooting a running system by taking an image of memory during some bad state, such as a transient performance problem or service outage. Note that this image of memory is imperfect due to changes that occur while the system is running. If the system is up and you can still run some commands, you can execute the savecore -L command to save the image of the system to the dump device and then immediately write out the crash dump files to your savecore directory. You can use the savecore -L command only if you have configured a dedicated dump device.

Configuring Your System for Crash Dumps

This section describes tasks for managing crash dump procedures for your system. Keep the following points in mind when you are working with system crash information:

- You must assume the root role to access and manage system crash information. See "Using Your Assigned Administrative Rights" in Securing Users and Processes in Oracle Solaris 11.3.
- Starting with the Oracle Solaris 11.3 release, when a system crashes, a copy of its physical memory can be held in RAM until the system reboots, then written to the file system. This process is called a *deferred dump*. If a deferred dump is not possible, the physical memory is written to a dump device during a crash. See "Crash Files Now Deferred Until After Reboot in Oracle Solaris 11.3" in *Troubleshooting System Administration Issues in Oracle Solaris* 11.3.
- Do not disable the option of saving system crash dump files on the system. System crash dump files provide an invaluable way to determine what is causing the system to crash.
- Dedicated ZFS volumes are used for swap and dump areas. For instructions, see "Managing ZFS Swap and Dump Devices" in *Managing ZFS File Systems in Oracle Solaris* 11.3.

Displaying the Current Crash Dump Configuration

To display the current crash dump configuration, assume the root role and issue the dumpadm command with no arguments.

dumpadm

```
Dump content: kernel with ZFS metadata
Dump device: /dev/zvol/dsk/rpool/dump (dedicated)
Savecore directory: /var/crash
Savecore enabled: yes
Save compressed: on
```

This example output shows the following configuration:

- The dump content is kernel memory pages with ZFS metadata.
- Kernel memory will either be held in memory until a reboot or dumped on a dedicated dump device, /dev/zvol/dsk/rpool/dump.
- System crash dump files will be saved in the /var/crash directory.
- Saving crash dump files is enabled.
- Crash dump files are saved in compressed format.

Modifying the Configuration for Crash Dumps

To modify the crash dump configuration, assume the root role and use the dumpadm command.

The syntax for the dumpadm command is as follows:

```
# /usr/sbin/dumpadm [-enpuy] [-c content-type] [-d dump-device] [-m mink | minm | min%]
[-s savecore-dir] [-r root-dir] [-z on | off]
```

-c content-type

Specifies the type of data to dump. The possible values are as follows:

- kernel which dumps the kernel memory pages only
- all which dumps all memory pages
- curproc which dumps kernel memory and the memory pages of the process whose thread was executing when the crash occurred
- allproc which dumps kernel memory pages and all process pages
- zfs which dumps kernel pages that store ZFS metadata

The default dump content is kernel memory with ZFS metadata. For example:

```
# dumpadm -c kernel
```

dumpadm -c +zfs
dumpadm -c -zfs
dumpadm -c curproc+zfs

-d dump-device

Specifies the device that stores dump data temporarily when the system crashes. The primary dump device is the default dump device. When the dump device is not the swap area, savecore runs in the background, which speeds up the boot process.

Note - A deferred dump will store dump data in RAM temporarily instead of using a dump device. However, you should specify a dump device in case the deferred dump fails, cannot be performed, or the savecore directory does not have enough space to write the crash dump files directly into the file system.

Prints an estimate of disk space required for storing a compressed crash dump. The value is computed using the current configuration and currently running system.

-m mink | minm | min%

-e

-n

-u

-у

-s savecore-dir

Specifies the minimum free disk space for saving crash dump files by creating a minfree file in the current savecore directory. This parameter can be specified in KB (mink), MB (minm) or file system size percentage (min%). If no minimum free space has been configured, the default is 1MB.

The savecore command consults this file prior to writing the crash dump files. If writing the crash dump files would decrease the amount of free space below the minfree threshold due to their size, the dump files are not written and an error message is logged. For information about recovering from this scenario, see "Saving Data When the Crash Dump Directory Is Full" on page 20.

Specifies that savecore not be run automatically when the system reboots. This dump configuration is not recommended because the system will attempt to preserve a crash dump image in memory.

-p Produces machine-readable output.

Specifies an alternate directory for storing crash dump files. In Oracle Solaris 11, the default directory is /var/crash.

Forcibly updates the kernel dump configuration based on the contents of the /etc/dumpadm.conf file.

Modifies the dump configuration to automatically execute the savecore command upon reboot, which is the default for this dump setting.

-z on | off

Modifies the dump configuration to control the operation of the savecore command upon reboot. The on setting enables the saving of a core file in a compressed format. The off setting automatically uncompresses the crash dump file. Because crash dump files can be extremely large and therefore require less file system space if they are saved in a compressed format, the default is on.

EXAMPLE 1 Modifying a Crash Dump Configuration

In this example, all of memory is dumped to the dedicated dump device, /dev/zvol/dsk/ rpool/dump, and the minimum free space that must be available after the crash dump files are saved is 10% of the file system space.

dumpadm

```
Dump content: kernel with ZFS metadata
       Dump device: /dev/zvol/dsk/rpool/dump (dedicated)
Savecore directory: /var/crash
  Savecore enabled: yes
  Save compressed: on
# dumpadm -c all -d /dev/zvol/dsk/rpool/dump -m 10%
       Dump content: all pages
       Dump device: /dev/zvol/dsk/rpool/dump (dedicated)
Savecore directory: /var/crash (minfree = 5935131KB)
  Savecore enabled: yes
   Save compressed: on
# dumpadm -n
```

Dump content: all pages Dump device: /dev/zvol/dsk/rpool/dump (dedicated) Savecore directory: /var/crash (minfree = 5935131KB)

Savecore enabled: no Save compressed: on

dumpadm -y

Dump content: all pages Dump device: /dev/zvol/dsk/rpool/dump(dedicated) Savecore directory: /var/crash (minfree = 5935131KB) Savecore enabled: yes

Save compressed: on

EXAMPLE 2 Disabling the Saving of Crash Dumps

This example illustrates how to disable the saving of crash dumps on your system.

dumpadm -n

```
Dump content: all pages
       Dump device: /dev/zvol/dsk/rpool/dump (dedicated)
Savecore directory: /var/crash (minfree = 5697105KB)
```

Savecore enabled: no Save compressed: on

Caution - Oracle Solaris strongly recommends that you do not disable the saving of crash dumps. Crash dumps provide an invaluable way to determine what causes your system to crash.

EXAMPLE 3 Enabling the Saving of Crash Dumps

This example illustrates how to enable the saving of crash dumps on your system.

Troubleshooting After a System Crashes

If an Oracle Solaris system crashes, you will want to provide as much information as possible, including general system information and the specific information provided in the crash dump files

To troubleshoot an existing crash dump, see the following:

- "What to Do If the System Crashes" on page 16
- "Examining Crash Dump Information" on page 17
- "Checklist for Troubleshooting a System Crash" on page 19
- "Saving Data When the Crash Dump Directory Is Full" on page 20

What to Do If the System Crashes

In the event of a system crash:

1. Write down the system console messages.

If a system crashes, making it run again might seem like your most pressing concern. However, before you reboot the system, examine the console screen for messages. These messages can provide some insight about what caused the crash. Even if the system reboots automatically and the console messages have disappeared from the screen, you might be able to check these messages by viewing the /var/adm/messages system error log file. For more information about viewing system error log files, see "Viewing System Messages and Logging" on page 41.

2. If you have frequent crashes and cannot determine the cause, gather all of the information you can from the system console or the /var/adm/messages file and have it ready for a customer support representative to examine.

For a complete list of troubleshooting information to gather for your service provider, see "Checklist for Troubleshooting a System Crash" on page 19.

3. Check to see if a system crash dump was generated after the system crash.

Caution - Do not remove important system crash information until it has been sent to your customer support representative.

4. If the system fails to boot after a system crash, see "Shutting Down and Booting a System for Recovery Purposes" in *Booting and Shutting Down Oracle Solaris 11.3 Systems* for further instructions.

Examining Crash Dump Information

You can examine the control structures, active tables, memory images of a live or crashed system kernel and other information about the operation of the kernel by using the mdb utility.

Note - The following procedure provides only a limited example of how to use the mdb utility. Using the mdb utility to its full potential requires a detailed knowledge of the kernel, and, is beyond the scope of this manual. For further information about using this utility, see the *Oracle Solaris Modular Debugger Guide* and mdb(1) man page.

▼ How to Examine Crash Dump Information

1. Assume the root role.

See "Using Your Assigned Administrative Rights" in *Securing Users and Processes in Oracle Solaris* 11.3.

2. Change to the directory where the crash dump information has been saved.

For example, to change to the default directory:

cd /var/crash

If you are unsure of the location of the crash dump, use the dumpadm command to determine where the system has been configured to store kernel crash dump files. The following sample output shows that the default directory location has not been changed:

/usr/sbin/dumpadm

Dump content: kernel with ZFS metadata

```
Dump device: /dev/zvol/dsk/rpool/dump (dedicated)
Savecore directory: /var/crash
Savecore enabled: yes
Save compressed: on
```

3. Examine the crash dump by using the modular debugger utility (mdb).

```
# /usr/bin/mdb [-k] crashdump-file
```

-k Specifies kernel debugging mode by assuming the file is an operating

system crash dump file.

crashdump-file Specifies the operating system crash dump file.

For example:

```
# /usr/bin/mdb -K vmcore.0
```

The command can also be specified as follows:

/usr/bin/mdb -k 0

4. Display the system crash status.

To use the ::system dcmd command when examining a kernel crash dump, the core file must be a kernel crash dump, and the -k option must have been specified when starting the mdb utility.

5. Quit the mdb utility.

> \$quit

Example 4 Examining Crash Dump Information

This example shows sample output from the mdb utility, which includes system information and identifies the tunables that are set in this system's /etc/system file.

```
# cd /var/crash
# /usr/bin/mdb -k unix.0
Loading modules: [ unix krtld genunix ip nfs ipc ptm ]
> ::status
debugging crash dump /dev/mem (64-bit) from ozlo
```

```
operating system: 5.10 Generic sun4v
> ::system
set ufs_ninode=0x9c40 [0t40000]
set ncsize=0x4e20 [0t20000]
set pt_cnt=0x400 [0t1024]
> $q
```

Checklist for Troubleshooting a System Crash

Answer the questions in the following checklist to help isolate the system problem and to prepare to consult with your Oracle Support providers.

Item	Your Data
Is a system crash dump available?	
Identify the operating system release and appropriate software application release levels.	
The user should receive information for more/etc/release or pkg info entire.	
Identify system hardware.	
Include the prtdiag output for SPARC and x86 systems. Include Explorer output, which is often requested by services for all systems.	
Are patches installed?	
Because Oracle Solaris 11 does not show showrev -p output, include information about installed SRUs & IDRs instead.	
Is the problem reproducible?	
A reproducible test case is often essential for debugging difficult problems. By reproducing the problem, the service provider can build kernels with special instrumentation to trigger, diagnose, and fix the bug.	
Does the system have any third-party drivers?	
Drivers run in the same address space as the kernel. With all the same privileges, they can cause system crashes if they have bugs.	
What was the system doing before it crashed?	
Unusual circumstances like running a new stress test or experiencing higher-than-usual load might have led to the crash.	
Did any unusual console messages display right before the system crashed?	
Sometimes the system will show signs of distress before it actually crashes; this information is often useful.	

Item Your Data

Did you add any parameters to the /etc/system file?

/etc/system is now supplemented by /etc/system.d/* starting with Oracle Solaris 11.2.

Did the problem start recently?

If so, did the onset of problems coincide with any changes to the system? For example: new drivers, new software, different workload, CPU upgrade, or a memory upgrade.

Saving Data When the Crash Dump Directory Is Full

 If system crashes with no room left in the savecore directory and you want to save some critical system crash dump information, use one of the following methods.

After the system reboots, log in as the root role. Remove existing crash dump files that have already been sent to your service provider from the savecore directory.

Note - The savecore directory is typically /var/crash.

Alternately, after the system reboots, log in as the root role. Manually run the savecore command and specify an alternate directory that has sufficient disk space:

savecore directory

Managing Incidents With Oracle Enterprise Manager Ops Center

It is necessary to manage incidents for physical and virtual operating systems, servers, and storage devices within a large deployment. Rather than just monitoring incidents within individual systems, you can use the comprehensive system management solutions available in the Oracle Enterprise Manager Ops Center.

Using the Enterprise Manager Ops Center, you can set up alerts that tell you when part of your data center is not performing as expected, manage these incident reports, and attempt repairs.

For more information, see Oracle Solaris Enterprise Manager.

Troubleshooting When a System Hangs or Rebooting Fails

This chapter describes what you can do when a system hangs or if you have problems rebooting a system.

It covers the following information:

- "What to Do If Rebooting Fails" on page 21
- "What to Do If You Forgot the root Password or Cannot Boot the System" on page 22
- "What to Do If a System Hang Occurs" on page 22

What to Do If Rebooting Fails

If the system does not reboot completely, or if the system reboots and then crashes again, a software or hardware problem might be preventing the system from booting successfully.

Cause of System Not Booting	How to Fix the Problem
The system can't find /platform/`uname -m`/kernel/sparcv9/unix.	You may need to change the boot-device setting in the PROM on a SPARC based system. For information about changing the default boot device, see "Displaying and Setting Boot Attributes" in Booting and Shutting Down Oracle Solaris 11.3 Systems.
The Oracle Solaris boot archive has become corrupted or the SMF boot archive service has failed. An error message is displayed if you run the svcs -x command.	Create a second boot environment that is a backup of the primary boot environment. In the event the primary boot environment is not bootable, boot the backup boot environment. Alternatively, you can boot from the Live CD or USB media.
An invalid entry is in the /etc/passwd file.	For information about recovering from an invalid passwd file, see "How to Boot From Media to Resolve an Unknown root Password" in <i>Booting and Shutting Down Oracle Solaris 11.3 Systems</i> .
The x86 boot loader (GRUB) is damaged or the GRUB menu is missing or has become corrupt.	For information about recovering from a damaged x86 boot loader or a missing or corrupt GRUB menu, see "How to Boot From Media to Resolve a Problem With the GRUB Configuration That Prevents the System From

Cause of System Not Booting	How to Fix the Problem	
	Booting" in Booting and Shutting Down Oracle Solaris 11.3 Systems.	
A hardware problem exists with a disk or another device.	Check the hardware connections:	
	■ Make sure the equipment is plugged in.	
	Make sure all the switches are set properly.	
	 Look at all the connectors and cables, including the Ethernet cables. 	
	■ If all these steps fail, turn off the power to the system, wait 10 to 20 seconds, and then turn on the power again.	

If none of the above suggestions solve the problem, contact your local service provider.

What to Do If You Forgot the root Password or Cannot Boot the System

If you forget the root password or experience another problem that prevents the system from booting, do the following:

- 1. Stop the system.
- 2. Follow the directions in "How to Boot From Media to Resolve an Unknown root Password" in *Booting and Shutting Down Oracle Solaris 11.3 Systems*.
- 3. If the root password is the problem, remove the root password from the /etc/shadow file.
- 4. Reboot the system.
- 5. Log in and set the root password.

What to Do If a System Hang Occurs

A system can freeze or hang rather than crash completely if a software process is stuck. Follow these steps to recover from a hung system.

- 1. If the system is running a window environment, follow these suggestions. If these suggestions do not solve the problem, go to step 2.
 - Make sure the pointer is in the window where you are typing the commands.
 - Press Control-Q in case the user accidentally pressed Control-S, which freezes the screen. Control-S freezes only the window, not the entire screen. If a window is frozen, try using another window.

- If possible, log in remotely from another system on the network. Use the pgrep command to look for the hung process. If the window system appears to be hung, identify the process and kill it.
- 2. Press Control-\ to force quit the running program and (probably) write out a core file.
- 3. Press Control-C to interrupt the program that might be running.
- 4. Log in remotely and attempt to identify and kill the process that is hanging the system.
- 5. Log in remotely, assume the root role, and then reboot the system.
- 6. If the system still does not respond, force a crash dump and reboot. For more information, see "Forcing a Crash Dump and Reboot of the System" in *Booting and Shutting Down Oracle Solaris* 11.3 Systems.
- 7. If the system still does not respond, turn the power off, wait a minute or so, and then turn the power back on.
- 8. If you cannot get the system to respond at all, contact your local service provider for help.

Troubleshooting File System Problems

This chapter describes how to fix file system issues including the following:

- "What to Do If a File System Fills Up" on page 25
- "What to Do If File ACLs Are Lost After Copy or Restore" on page 26
- "Troubleshooting File Access Problems" on page 26

What to Do If a File System Fills Up

When the root (/) file system or any other file system fills up, you will see the following message in the console window:

```
... file system full
```

There are several reasons why a file system fills up. The following sections describe several scenarios for recovering from a full file system.

File System Fills Up Because a Large File or Directory Was Created

Cause: Someone accidentally copied a file or directory to the wrong location or an application crashed and wrote a large core file to the file system.

Solution: Log in and assume the root role, then use the ls -tl command in the file system to identify which large file is newly created and then remove it.

A ZFS File System Is Full Because the System Ran Out of Memory

Cause: A ZFS file system is trying to record changes while preserving the file in a previous snapshot, thereby using more memory than allowed.

Solution: Remove files from the ZFS file system to free up disk space. For more information, see "Resolving ZFS Space Issues" in *Managing ZFS File Systems in Oracle Solaris 11.3*.

A TMPFS File System Is Full Because the System Ran Out of Memory

Cause: If a TMPFS file system is trying to write more than is allowed or current processes are using a lot of memory.

Solution: For information about recovering from tmpfs-related error messages, see the tmpfs(7FS) man page.

What to Do If File ACLs Are Lost After Copy or Restore

Cause: Files or directories with ACLs were copied or restored into the /tmp directory and the ACL attributes were lost. The /tmp directory is usually mounted as a temporary file system, which doesn't support UFS file system attributes such as ACLs.

Solution: Copy or restore files into the /var/tmp directory instead.

Troubleshooting File Access Problems

Users who cannot access a program, a file, or a directory that they could previously use often call on a system administrator for help:

When you encounter such a problem, investigate one of three areas:

- Whether the user's search has been changed or the directories in the search path are not in the proper order.
- Whether the file or directory has the proper permissions or ownership.
- Whether the configuration of a system accessed over the network has changed.

This chapter briefly describes how to recognize problems in each of these three areas and suggests possible solutions.

Solving Problems With Search Paths

When you try to access a command, you might get the wrong version of the command or the message Command not found might display.

In order to fix a search path problem, you need to know the pathname of the directory where the command is stored. Check the man page for the command to see its typical location.

Accessing an Incorrect Version of the Command

If the wrong version of the command is found, a directory including the same command name is in your search path. The correct directory might appear later in the search path or may not be included at all.

▼ How to Diagnose and Correct Search Path Problems

1. Determine which version of the command you are using.

For example:

\$ which acroread
/usr/bin/acroread

2. Display the current search path.

\$ echo \$PATH

- Check the current search path to see whether the correct directory is included and whether other directories including the same command name are listed before the correct directory.
- 4. In the path listed in the .profile file in your home directory, either add the correct directory or move the correct directory to earlier in the path.

Use a colon to separate path names.

(Optional) If you need to use the command before your next system login, activate the new path.

```
$ . $HOME/.profile
```

6. (Optional) If you have activated the new path, verify that the command will be accessed through the correct path.

\$ which command

Accessing Commands That Are Not Found

The error message Command Not Found is displayed for one of the following reasons:

- The command is not available on the system
- The command directory is not in the search path

If the command is not available on the system, contact your system administrator.

▼ How to Include a Search Path in Your Path

1. Display the current search path and make sure that the directory for the command is not in your path or that the path is not misspelled.

echo \$PATH

- 2. Add the directory for the command to the PATH entry in the \$HOME/.profile file.
 - Use a colon to separate path names.
- 3. Activate the new path.
 - \$. \$HOME/.profile
- 4. Verify that the correct path is now displayed for the command.
 - \$ which command

Changing File and Group Ownerships

Frequently, file and directory ownerships change because someone edited the files as an administrator. When you create home directories for new users, be sure to make the user the owner of the dot (.) file in the home directory. When users do not own "." they cannot create files in their own home directory.

Access problems can also arise when the group ownership changes or when a group of which a user is a member is deleted from the /etc/group database.

For information about how to change the permissions or ownership of a file that you are having problems accessing, see Chapter 1, "Controlling Access to Files" in *Securing Files and Verifying File Integrity in Oracle Solaris* 11.3.

Solving File Access Problems

When users cannot access files or directories that they previously could access, the permissions or ownership of the files or directories probably has changed.

Recognizing Problems With Network Access

If users have problems using the rcp remote copy command to copy files over the network, the directories and files on the remote system may have restricted access by setting permissions. Another possible source of trouble is that the remote system and the local system are not configured to allow access.

See "Strategies for NFS Troubleshooting" in *Managing Network File Systems in Oracle Solaris* 11.3 for information about problems with network access and problems with accessing systems through AutoFS.

• • • CHAPTER 4

Prepare for Possible Process Failures by Using Core Files

This chapter describes how to set up the specifications for the core files that a system produces when a process fails and how to examine these core files after a failure. It includes the following information:

- "About Process Failures and Core Files" on page 31
- "Parameters for Core File Creation" on page 32
- "Administering Your Core File Specifications" on page 33
- "Examining Core Files After a Process Failure" on page 37

About Process Failures and Core Files

When a process or application terminates abnormally, the system automatically generates a set of files. This process can be described as a *core dump*. The files that are created are *core files*. A core file is a disk copy of the contents of the process address space at the time of its termination, along with additional information about the state of the process. Typically, core files are produced following abnormal termination of a process resulting from a bug in the corresponding application. A core file provides invaluable information for you to use in diagnosing the problem that cause the process failure. See "Parameters for Core File Creation" on page 32.

As part of your ongoing system administration, you can use the coreadm command to control the creation specifications for core files. For example, you can use the coreadm command to configure a system so that all process core files are placed in a single system directory and you can easily track problems. See "Administering Your Core File Specifications" on page 33.

When a process terminates abnormally, you can inspect the core files that are created using a debugger such as mdb or by using a proc tool. See "Examining Core Files After a Process Failure" on page 37.

Parameters for Core File Creation

When a process fails, the system tries to create up to two core files for each failed process, using a global core file name pattern and a per-process core file name pattern to create each core file name. The coreadm command controls these name patterns and specifies the location of the core files. This section describes some of the file path and file name parameters. For a full description of the core dump process, see the core(4) man page. For the full description of the coreadm options, see the coreadm(1M) man page.

Configurable Core File Paths

When a process terminates abnormally, it produces a core file in the current directory by default. If the global core file path is enabled, each abnormally terminating process might produce two files, one in the current working directory and another in the global core file location. The file paths that are used are configurable parameters.

Two configurable core file paths can be enabled or disabled independently of each other as follows:

- A per-process core file path, which defaults to core and is enabled by default. If enabled, the per-process core file path causes a core file to be produced when the process terminates abnormally. The per-process path is inherited by a new process from its parent process.
 - When generated, a per-process core file is owned by the owner of the process with read/write permissions for the owner. Only the owning user can view this file.
- A global core file path, which defaults to core and is disabled by default. If enabled, an
 additional core file with the same content as the per-process core file is produced by using
 the global core file path.
 - When generated, a global core file is owned by root, with read/write permissions for root *only*. Non-privileged users cannot view this file.

Note - By default, a setuid process does not produce core files using either the global or perprocess path.

Expanded Core File Names

The name of a core file contains fields with information about the failed process. For a full description of the core file name fields, see the coreadm(1M) man page. This section focuses on the global variables.

If a global core file directory is enabled, core files can be distinguished from one another by using the following variables:

%d	Executable file directory name, up to a maximum of MAXPATHLEN characters
%f	Executable file name, up to a maximum of MAXCOMLEN characters
%g	Effective group ID
%m	Machine name (uname -m)
%n	System node name (uname -n)
%p	Process ID
%t	Decimal value of time(2)
%u	Effective user ID
%Z	Name of the zone in which process is executed (zonename)
%%	Literal %

For example, suppose /var/core/core.%f.%p is set as the global core file path. If a sendmail process with PID 12345 terminates abnormally, it would produce /var/core/core.sendmail.12345 as the core file.

Improving Core File Dump Performance

You can improve the performance of core file dumping on a system by excluding some parts of a process's binary image from the core dump. When you use the coreadm command to customize your core dump specifications, you could specify exclusion of, for example, DISM mappings, or ISM mappings, or System V shared memory from a core dump. For more information, see the coreadm(1M) man page.

Administering Your Core File Specifications

This section provides the following information about managing core files:

- "Displaying the Current Core Dump Configuration" on page 34
- "Setting the Core File Name Pattern" on page 34
- "Enabling File Paths" on page 35

- "Enabling setuid Programs to Produce Core Files" on page 35
- "Reverting to the Default Core File Settings" on page 36
- "Correcting Obsolete Core File Parameters" on page 36

Displaying the Current Core Dump Configuration

Use the coreadm command without any options to display the current core dump configuration.

\$ coreadm

```
global core file pattern:
global core file content: default
init core file pattern: core
init core file content: default
global core dumps: disabled
per-process core dumps: enabled
global setid core dumps: disabled
per-process setid core dumps: disabled
global core dump logging: disabled
```

Setting the Core File Name Pattern

You can set a core file name pattern on a global, zone, or per-process basis. In addition, you can set per-process defaults that persist across a system reboot.

For example, the following coreadm command sets the default per-process core file pattern for all processes that are started by the init process. This setting applies to all processes that have not explicitly overridden the default core file pattern. This setting persists across system reboots.

```
# coreadm -i /var/core/core.%f.%p
```

The following coreadm command sets the per-process core file name pattern for any processes:

```
# coreadm -p /var/core/core.%f.%p $$
```

The \$\$ symbols represent a placeholder for the process ID of the currently running shell. The per-process core file name pattern is inherited by all child processes.

For example:

```
$ coreadm -p $HOME/corefiles/%f.%p $$
```

Alternately, you could assume the root role and set a global file name pattern:

```
# coreadm -g /var/corefiles/%f.%p
```

After a global or per-process core file name pattern is set, it must be enabled with the coreadm -e command.

You can set the core file name pattern for all processes that are run during a user's login session by putting the command in a user's initialization file, for example, .profile.

Enabling File Paths

You can enable a per-process or global core file path.

To enable a per-process core file path, assume the root role and issue the following command:

```
# coreadm -e process
```

If you want to verify the configuration, display the current process core file path.

```
# coreadm $$
1180: /home/kryten/corefiles/%f.%p
```

To enable a global core file path, assume the root role and issue the following command:

```
# coreadm -e global -g /var/core/core.%f.%p
```

If you want to verify the configuration, display the current process core file path.

coreadm

```
global core file pattern: /var/core/core.%f.%p
global core file content: default
init core file pattern: core
init core file content: default
global core dumps: enabled
per-process core dumps: enabled
global setid core dumps: disabled
per-process setid core dumps: disabled
global core dump logging: disabled
```

Enabling setuid Programs to Produce Core Files

You can use the coreadm command to enable or disable setuid programs to produce core files for all system processes or on a per-process basis by setting the appropriate path.

• If the global setuid option is enabled, a global core file path allows all setuid programs on a system to produce core files.

 If the per-process setuid option is enabled, a per-process core file path allows specific setuid processes to produce core files.

By default, both flags are disabled. For security reasons, the global core file path must be a full pathname starting with a leading /. If root disables per-process core files, individual users cannot obtain core files.

The setuid core files are owned by root, with read/write permissions for root only. Regular users cannot access these files even if the process that produced the setuid core file is owned by an ordinary user.

For more information, see the coreadm(1M) man page.

Reverting to the Default Core File Settings

As root, run one of the following commands to disable the core file path and remove the core file name pattern.

• For global core file settings:

```
# coreadm -d global -g ""
```

Note - "" is an empty string with no space.

For per-process core file settings:

```
# coreadm -d process -g ""
```

The -d option disables the core file path. The -g option with the empty string variable removes the core file name pattern. The core file path and core file name pattern are returned to the original default settings.

Correcting Obsolete Core File Parameters

If you have an obsolete parameter that allows setuid core files in your /etc/system file, the following message appears:

```
NOTICE: 'set allow_setid_core = 1' in /etc/system is obsolete NOTICE: Use the coreadm command instead of 'allow_setid_core'
```

To correct this problem, remove allow_setid_core=1 from the /etc/system file. Then use the coreadm command to enable global setuid core file paths.

Examining Core Files After a Process Failure

The proc tools enable you to examine process core files as well as live processes. The proc tools are utilities that can manipulate features of the /proc file system.

You can apply /usr/proc/bin/pstack, pmap, pldd, pflags, and pcred tools to core files by specifying the name of the core file on the command line, similar to the way you specify a process ID to these commands.

For more information about using the proc tools to examine core files, see the proc(1).

EXAMPLE 5 Examining Core Files With the proc Tools

Managing System Logs and Messaging

This chapter describes how to view and manage system logs and system messages. It covers the following information:

- "About System Logs and Messaging" on page 39
- "Extended System Logging With the rsyslogd Command" on page 44
- "System Message Formats" on page 40
- "System Log Rotation" on page 41
- "Customizing System Message Logging" on page 42
- "Enabling Remote Console Messaging" on page 45

About System Logs and Messaging

The syslogd command enables system message display and forwarding capabilities. It reads and forwards system messages to the appropriate log files or users, based on the priority of a message and the location of its system facility. While the syslog configuration file controls where messages are forwarded to, the syslogd command logs a timestamp for every message with interval minutes. Note that the default interval time is set to 20 minutes.

If you want to grant non-root users the privilege of maintaining log files, you can grant Log Management as a rights profile for that user. You can make that grant by using the -P option with either the useradd command for new users or the usermod command for an existing user. For instructions, see the useradd(1M) and the usermod(1M) man pages.

Managing System Messages and Logging

This section describes the system messaging features in Oracle Solaris.

System Message Formats

System messages display on the console device. The text of most system messages has the following format:

```
[ID msgid facility.]
```

For example:

```
[ID 672855 kern.notice] syncing file systems...
```

If the message originated in the kernel, the kernel module name is displayed. For example:

```
Oct 1 14:07:24 mars ufs: [ID 845546 kern.notice] alloc: /: file system full
```

When a system crashes, it might display a panic message on the system console, formatted as follows:

```
panic: error message
```

Less frequently, the following message might be displayed instead of the panic message:

```
Watchdog reset !
```

System Message Logging

The error logging daemon, syslogd, automatically records various system warnings and errors in message files. By default, many of these system messages are displayed on the system console and are stored in the /var/adm directory. You can direct where these messages are stored by setting up system message logging. For more information, see "Customizing System Message Logging" on page 42. These messages can alert you to system problems, such as a device that is about to fail.

The /var/adm directory contains several message files. The most recent messages are in /var/adm/messages file (and in messages.*), and the oldest are in the messages.3 file. After a period of time (usually every ten days), a new messages file is created. The messages.0 file is renamed messages.1 is renamed messages.2, and messages.2 is renamed messages.3. The current /var/adm/messages.3 file is deleted.

Because the /var/adm directory stores large files containing messages, crash dumps, and other data, this directory can consume lots of disk space. To keep the /var/adm directory from growing too large, and to ensure that future crash dumps can be saved, you should remove unneeded files periodically. You can automate this task by using the crontab file. For more information about automating this task, see "Removing Dump Files" in *Managing Devices in Oracle Solaris 11.3* and Chapter 4, "Scheduling System Tasks" in *Managing System Information, Processes, and Performance in Oracle Solaris 11.3*.

Viewing System Messages and Logging

To display recent messages generated by a system crash or reboot, use the dmesg command.

```
$ dmesq
```

\$ dmesq

For large message logs, use the more command to display only one screen of messages at a time.

```
$ more /var/adm/messages
```

EXAMPLE 6 Viewing System Messages

The following example shows output from the dmesg command on an Oracle Solaris 11 system.

```
Mon Sep 13 14:33:04 MDT 2010

Sep 13 11:06:16 sr1-ubrm-41 svc.startd[7]: [ID 122153 daemon.warning] ...

Sep 13 11:12:55 sr1-ubrm-41 last message repeated 398 times

Sep 13 11:12:56 sr1-ubrm-41 svc.startd[7]: [ID 122153 daemon.warning] ...

Sep 13 11:15:16 sr1-ubrm-41 last message repeated 139 times
```

Sep 13 11:15:16 sr1-ubrm-41 xscreensaver[25520]: ...
Sep 13 11:15:17 sr1-ubrm-41 svc.startd[7]: [ID 122153 daemon.warning]...
.

For more information, see the dmesg(1M) man page.

Sep 13 11:15:16 sr1-ubrm-41 xscreensaver[25520]: ,,,

System Log Rotation

System log files are rotated by the logadm command from an entry in the root crontab file. The /usr/lib/newsyslog script is no longer used.

The system log rotation is defined in the /etc/logadm.conf file. This file includes log rotation entries for processes such as syslogd. For example, suppose one entry in the /etc/logadm.conf file specifies that the /var/log/syslog file is rotated weekly unless the file is empty. The most recent syslog file becomes syslog.0, the next most recent becomes syslog.1, and so on. Eight previous syslog files are kept.

The /etc/logadm.conf file also contains time stamps of when the last log rotation occurred.

You can use the logadm command to customize system logging and to add additional logging in the /etc/logadm.conf file as needed. Note that you must first assume root or a role that has syslog.conf authorization.

For example, to rotate the Apache access and error logs, you would use the following commands:

```
# logadm -w /var/apache/logs/access_log -s 100m
# logadm -w /var/apache/logs/error log -s 10m
```

In this example, the Apache access_log file is rotated when it reaches 100 MB in size, with a .0, .1, (and so on) suffix, keeping ten copies of the old access_log file. The error_log is rotated when it reaches 10 MB in size with the same suffixes and number of copies as the access log file.

The /etc/logadm.conf entries for the Apache log rotation examples look similar to the following example:

```
# cat /etc/logadm.conf
.
.
.
/var/apache/logs/error_log -s 10m
/var/apache/logs/access log -s 100m
```

For more information, see the logadm(1M).

Customizing System Message Logging

You can capture additional error messages that are generated by various system processes by modifying the /etc/syslog.conf file. By default, the /etc/syslog.conf file directs many system process messages to the /var/adm/messages files, which also contain crash and boot messages. To view /var/adm messages, see "Viewing System Messages and Logging" on page 41.

The /etc/syslog.conf file contains two columns separated by tabs:

facility.level ... action

facility.level

A *facility* is a system source of the message or condition. May be a comma-separated list of facilities. A *level* indicates the severity or priority of the condition being logged.

Do not put two entries for the same facility on the same line if the entries are for different priorities. Putting a priority in the syslog file indicates that all messages of at least that priority are logged, with the last message taking precedence. For a given facility and level, syslogd matches all messages for that level and all higher levels.

action

Indicates where the messages are forwarded.

The following example shows sample lines from a default /etc/syslog.conf file.

These entries cause the following user messages to be logged automatically:

- User errors are printed to the console and also are logged to the /var/adm/messages file.
- User messages requiring immediate action (alert) are sent to the root and operator users.
- User emergency messages are sent to individual users.

Note - Placing entries on separate lines might cause messages to be logged out of order if a log target is specified more than once in the /etc/syslog.conf file. Note that you can specify multiple selectors in a single line entry, each separated by a semicolon.

The most common error condition sources are:

kern The kernel

auth Authentication

daemon All daemons

mail Mail system

lp Spooling system

user User processes

Note - The number of syslog facilities that can be activated in the /etc/syslog.conf file is unlimited.

The most common priority levels for syslog.conf messages, in priority order, are:

emerg System emergencies

alert Errors requiring immediate correction

crit Critical errors

err Other errors

info Informational messages

debug Output used for debugging

none This setting doesn't log output

▼ How to Customize System Message Logging

 Assume the root role or a role that has the solaris.admin.edit/etc/syslog.conf authorization assigned to it.

See "Using Your Assigned Administrative Rights" in Securing Users and Processes in Oracle Solaris 11.3.

2. Use the pfedit command and edit the /etc/syslog.conf file.

You can add or change message sources, priorities, and message locations. For more information, see the syslog.conf(4).

\$ pfedit /etc/syslog.conf

Save the changes.

Example 7 Customizing System Message Logging

This example shows a entry for a /etc/syslog.conf user.emerg facility that sends user emergency messages to root and individual users.

user.emerg `root, *'

Extended System Logging With the rsyslogd Command

This Oracle Solaris release includes the option of installing and using the rsyslogd package for managing system logging. rsyslogd is derived from the syslogd daemon implementation, with a modular design that supports several features such as filtering, TCP, encryption, and high-precision time-stamps, as well as output control.

The syslog SMF service, svc:/system/system-log:default, continues to be the default logging service. To use the rsyslog service, you need to install the rsyslog package and enable the rsyslogd service.

▼ How to Install and Enable rsyslog

1. Check whether the rsyslog package is already installed on your system by trying to enable the service as follows:

root@pcclone: ~# svcadm enable svc:/system/system-log:rsyslog

If the rsyslog package is not installed, the following message displays:

svcadm: Pattern 'svc:/system/system-log:rsyslog' doesn't match any instance.

2. If the rsyslog package is not installed, install it.

DOWNLOAD	PKGS	FILES	XFER (MB)	SPEED
Completed	3/3	68/68	1.7/1.7	354k/s

PHASE	ITEMS
Installing new actions	147/147
Updating package state database	Done
Updating package cache	0/0
Updating image state	Done
Creating fast lookup database	Done

3. Confirm the rsyslog instance.

This output confirms that the rsyslog instance exists, though it is disabled.

4. Switch to the rsyslog service.

```
root@pcclone:~# svcadm disable svc:/system/system-log:default
root@pcclone:~# svcadm enable svc:/system/system-log:rsyslog
root@pcclone:~# svcs -xv
```

These commands disable the default service, enable rsyslog, and report on status.

Next Steps

After rsyslog is installed and enabled, you can configure syslog in the /etc/rsyslog.conf file. For more information, see rsyslogd(1m).

Enabling Remote Console Messaging

The following console features improve your ability to troubleshoot Oracle Solaris remote systems:

The consadm command enables you to select a serial device as an auxiliary (or remote) console. Using the consadm command, a system administrator can configure one or more serial ports to display redirected console messages and to host sulogin sessions when the

system transitions between run levels. This feature enables you to dial in to a serial port with a modem to monitor console messages and participate in init state transitions. For more information, see sulogin(1M) and the step-by-step procedures that follow.

Although you can log in to a system using a port configured as an auxiliary console, it is primarily an output device displaying information that is also displayed on the default console. If boot scripts or other applications read and write to and from the default console, the write output displays on all the auxiliary consoles. But the input is only read from the default console. For more information, see "Guidelines for Using the consadm Command During an Interactive Login Session" on page 47.

- Console output now consists of kernel and syslog messages written to a new pseudo device, /dev/sysmsg. In addition, rc script startup messages are written to /dev/msglog. Previously, all of these messages were written to /dev/console.
 - Scripts that direct console output to /dev/console need to be changed to /dev/msglog if you want to see script messages displayed on the auxiliary consoles. Programs referencing /dev/console should be explicitly modified to use syslog() or strlog() if you want messages to be redirected to an auxiliary device.
- The consadm command runs a daemon to monitor auxiliary console devices. Any display device designated as an auxiliary console that disconnects, hangs up, or loses carrier is removed from the auxiliary console device list and is no longer active. Enabling one or more auxiliary consoles does not disable message display on the default console; messages continue to display on /dev/console.
- The consadm daemon does not start monitoring the port until after you add the auxiliary console with the consadm command. As a security feature, console messages are redirected only until the carrier drops or the auxiliary console device is deselected. Therefore, the carrier must be established on the port before you can successfully use the consadm command.

Using Auxiliary Console Messaging During Run Level Transitions

Note the following information when using auxiliary console messaging during run level transitions:

- Input cannot come from an auxiliary console if user input is expected for an rc script that is run when a system is booting. The input must come from the default console.
- The sulogin program, invoked by init to prompt for the root password when transitioning between run levels, has been modified to send the root password prompt to each auxiliary device in addition to the default console device.
- The user should never directly invoke sulogin. The user must have the solaris.system.
 maintenance authorization to use this utility.
- When the system is in single-user mode and one or more auxiliary consoles are enabled using the consadm command, a console login session runs on the first device to supply the

- correct root password to the sulogin prompt. When the correct password is received from a console device, sulogin disables input from all other console devices.
- A message is displayed on the default console and the other auxiliary consoles when one of the consoles assumes single-user privileges. This message indicates which device has become the console by accepting a correct root password. If there is a loss of carrier on the auxiliary console running the single-user shell, one of two actions might occur:
 - If the auxiliary console represents a system at run level 1, the system proceeds to the default run level.
 - If the auxiliary console represents a system at run level S, the system displays the ENTER RUN LEVEL (0-6, s or S): message on the device where the init s or shutdown command had been entered from the shell. If that device also has no carrier, you will have to re-establish the carrier and enter the correct run level. The init or shutdown command will not display the run-level prompt again.
- If you are logged in to a system using a serial port and an init or shutdown command is issued to transition to another run level, the login session is lost regardless of whether this device is the auxiliary console. This situation is identical to releases without auxiliary console capabilities.
- Once a device is selected as an auxiliary console using the consadm command, it remains the auxiliary console until the system is rebooted or the auxiliary console is deselected. However, the consadm command includes an option to set a device as the auxiliary console across system reboots. For more information, see the following procedure.

Guidelines for Using the consadm Command During an Interactive Login Session

You can run an interactive login session by logging in to a system using a terminal that is connected to a serial port and then using the consadm command to see the console messages from the terminal. Note the following behavior:

- If you use the terminal for an interactive login session while the auxiliary console is active, the console messages are sent to the /dev/sysmsg or /dev/msglog devices.
- While you issue commands on the terminal, input goes to your interactive session and not to the default console (/dev/console).
- If you run the init command to change run levels, the remote console software kills your interactive session and runs the sulogin program. At this point, input is accepted only from the terminal and is treated as if it is coming from a console device. This process allows you to enter your password to the sulogin program as described in "Using Auxiliary Console Messaging During Run Level Transitions" on page 46.

If you enter the correct password on the auxiliary terminal, the auxiliary console runs an interactive sulogin session and locks out the default console and any competing auxiliary console. This behavior means that the terminal essentially functions as the system console.

From here you can change to run level 3 or go to another run level. If you change run levels, sulogin runs again on all console devices. If you exit or specify that the system should come up to run level 3, then all auxiliary consoles lose their ability to provide input. They revert to being display devices for console messages.

As the system is coming up, you must provide information to rc scripts on the default console device. After the system comes back up, the login program runs on the serial ports and you can log back into another interactive session. If you've designated the device to be an auxiliary console, you will continue to get console messages on your terminal, but all input from the terminal goes to your interactive session.

▼ How to Display a List of Auxiliary Consoles

1. Issue the consadm command as root, with no arguments.

See "Using Your Assigned Administrative Rights" in Securing Users and Processes in Oracle Solaris 11.3.

- 2. Select one of the following steps:
 - a. Displays a list of auxiliary consoles.

```
# consadm
/dev/term/a
```

b. To display a list of persistent auxiliary consoles, use the -p option.

```
# consadm -p
/dev/term/b
```

▼ How to Enable an Auxiliary (Remote) Console

1. Log in to the system and assume the root role.

See "Using Your Assigned Administrative Rights" in *Securing Users and Processes in Oracle Solaris* 11.3.

2. Enable the auxiliary console.

```
# consadm -a device name
```

3. Verify that the current connection is the auxiliary console.

consadm

Example 8 Enabling an Auxiliary (Remote) Console

```
# consadm -a /dev/term/a
```

consadm
/dev/term/a

▼ How to Enable an Auxiliary (Remote) Console Across System Reboots

1. Log in to the system and assume the root role.

See "Using Your Assigned Administrative Rights" in Securing Users and Processes in Oracle Solaris 11.3.

2. Enable the auxiliary console across system reboots.

```
# consadm -a -p device name
```

This command adds the device to the list of persistent auxiliary consoles.

3. Verify that the device has been added to the list of persistent auxiliary consoles.

consadm

Example 9 Enabling an Auxiliary (Remote) Console Across System Reboots

```
# consadm -a -p /dev/term/a
# consadm
/dev/term/a
```

▼ How to Disable an Auxiliary (Remote) Console

1. Log in to the system and assume the root role.

See "Using Your Assigned Administrative Rights" in *Securing Users and Processes in Oracle Solaris* 11.3.

2. Disable the auxiliary console.

```
# consadm -d devicename
```

To also remove the auxiliary console from the list of persistent auxiliary consoles, add the -p option.

```
\# consadm -p -d devicename
```

3. Verify that the auxiliary console has been disabled.

consadm

Example 10 Disabling an Auxiliary (Remote) Console

consadm -d /dev/term/a
consadm
